

1 **THE ARCHITECTURE OF GREEN ENERGY SYSTEMS***

2 MICHAEL C. FERRIS[†] AND ANDY PHILPOTT [‡]

3 **Abstract.** Energy production throughout the world is transitioning from fossil fuels to renewable
4 sources such as wind power and solar power. This transition has been gradual - over half of the world's
5 electricity is still produced by coal, oil and gas - but must accelerate to meet global emission targets.
6 This paper examines the contributions that mathematical modelling can make to help accelerate this
7 transition. The models we catalog are confined to optimization and equilibrium models, but cover
8 a range of physical scales and time scales. Our focus is on novel model formulations that can help
9 overcome the challenges of the transition by unpicking the complexity inherent in many settings and
10 quantifying the tradeoffs that must be made when developing energy policy.

11 **Key words.** green energy transition, renewable electricity, carbon prices

12 **MSC codes.** 49-02, 65K10, 90C90, 91B74

13 **1. Introduction.** The world is undergoing a transition from using fossil-fuel
14 energy that emits greenhouse gases (mainly carbon dioxide) to using energy that
15 does not. This transition is a global response to calls to limit global warming that
16 has been caused by the emission of greenhouse gases over the post-industrial era.
17 The current scale and speed of this transition appears insufficient to keep global
18 temperatures below agreed targets. There are many technical, economic, social and
19 political reasons for this slowness that have been canvased in a number of recent
20 reports (see e.g., [1, 2, 10]).

21 Our purpose in this paper is to examine the contribution that mathematics and
22 mathematical models can make to achieving the goals of the transition and to under-
23 standing and overcoming the barriers that are faced in the transition. Those barriers
24 include affordability, sustainability, reliability, industrial competitiveness, and trusted
25 information. The contribution of the paper is primarily to present mathematics; it
26 is not intended to be a survey of existing energy models, of which there are many
27 (see, e.g., [67, 27]). Care is needed since differences between precise mathematical
28 definitions and socially accepted descriptions can lead to confusion and discord. For
29 example, reliability is a complex notion and can include aspects of robustness, resource
30 adequacy and resilience.

31 In particular we will focus on what we call the *architecture* of energy systems,
32 which consists not only of the physical infrastructure for generating and transporting
33 energy, but also the market and contractual arrangements that give incentives for
34 investing in this infrastructure and that allow for it to be operated in an efficient
35 manner. Our aim is not so much to deliver the correct answer or define an optimal
36 solution, but rather to pose questions that can benefit from a mathematical modelling
37 approach. Many of our approaches incorporate techniques to promote flexibility [20],
38 including multiple types of dispatchable generation, demand response, energy storage
39 and enhanced connectivity. While there are many different mathematical techniques

40 that could impact the transition, we will focus primarily on optimization, including
41 aspects of game theory and links to machine learning (forecasting and prediction) and
42 simulation approaches.

43 We are interested in the architecture of systems that generate mainly *green* energy,
44 a catch-all term that encompasses renewable energy from sources that are constantly
45 and naturally renewed such as hydroelectric power, wind power and solar power,
46 and energy from other sources with negligible carbon emissions (such as nuclear and
47 geothermal electricity), or net-zero emissions (such as biofuels). Such systems will be
48 an essential part of the transition, along with new technologies that fill gaps in our
49 operating landscape.

50 Our use of the adjective green in this context might be viewed by some as con-
51 tentious, as some activities associated with green energy production (such as building
52 hydroelectric dams or mining lithium) can damage the natural environment. As we
53 discuss later in the paper, some of this damage might be justifiable when traded off
54 against the damage avoided by reducing carbon emissions, so it would be unwise to
55 preclude such activities from the mix of green energy we study.

56 Designing the green energy system of the future is a global problem involving
57 interactions between countries across the world and requiring long term investments,
58 changes of operational procedures, trade-offs and innovations. While internationally
59 coordinated efforts are likely to be the most effective and economical, this is ham-
60 pered by political discord, disparate goals and perspectives on the severity of the
61 issue, and different ideas on the best course of action to transition into a green energy
62 system. Even within countries, different agents view the risk of inaction, or incorrect
63 actions, in contrasting ways, and will make decisions in their own interests in response
64 to incentives and regulations. At both of these scales (national and individual), de-
65 sired outcomes of fairness and equity require careful analysis and can be informed by
66 mathematical modelling using metrics that capture the goals.

67 The challenge then lies mainly in designing appropriate incentives and regulations,
68 so agents with different attitudes to risk align their actions with the objective of global
69 emissions reduction. Our approach in this paper is to look at tools that capture the
70 risk in each agents problems, suggest models and approaches to invest in a portfolio
71 of technologies that may reduce the variability in outcomes and enhance the ability to
72 finance their adoption, whilst quantifying the differences between these agent-driven
73 results and one that might arise with a system-wide perspective.

74 A green energy system can be viewed along three orthogonal dimensions. We
75 show two of these in Figure 1.

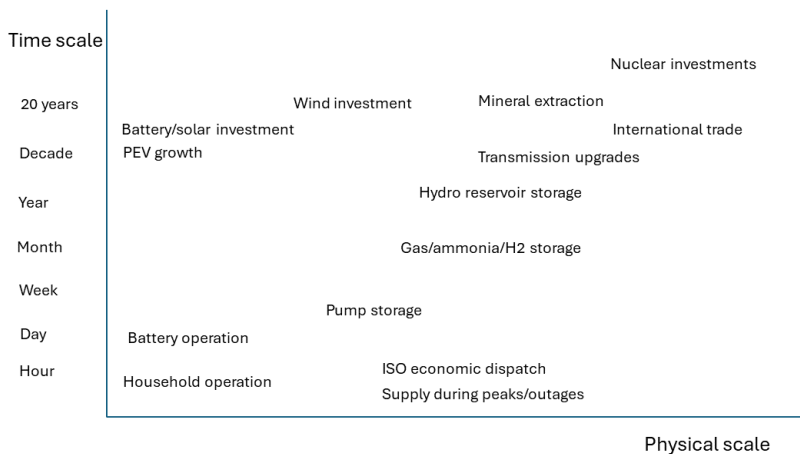

FIG. 1. *The energy transition in two dimensions*

76 In one dimension one can vary the physical scale of the system. At the smallest
 77 scale, one might consider a household with solar panels, a battery and a plug-in elec-
 78 tric vehicle. This could form part of a micro grid, which in turn connects to a larger
 79 system with industrial electricity supply and demand. High voltage electricity trans-
 80 mission lines link these together into an electricity network, that may be connected
 81 to neighbouring networks by transfers along tie lines. The system might transport
 82 energy from place to place using other carriers such as hydrogen, ammonia, natural
 83 gas, oil, coal or uranium. Transfers of energy are accompanied by financial flows,
 84 and derivative instruments that derive their value from these transactions. At the
 85 largest (global) scale the energy and financial flows are between different regions and
 86 economies; the design and operation of new forms of contracts and financial flows are
 87 critical to enabling the transition process.

88 The overall system is a collection of technologies at different physical scales, con-
 89 nected through a network that might be electrical or some other energy transport. To
 90 answer questions about the architecture of this system, or the design and operation
 91 of a component, one can consider a particular scale, in which case the interplay with
 92 larger (or smaller) scales needs to determine boundary interactions. Such boundary
 93 interactions may be physical, financial, regulatory or involve some form of incentives.
 94 Interactions occur among sectors of the economy including transport, buildings, in-
 95 dustry and agriculture, and reuse and disposal of raw materials necessary for the
 96 technologies must also be considered. Furthermore, specific mathematical models
 97 may be needed to capture the details of the technologies with some formulations be-
 98 ing a more accurate representation of reality, while others are approximations with
 99 properties amenable to deeper analysis.

100 The second important dimension to consider is time, and implicitly the evolution
 101 of uncertainties over varying time scales. Energy is produced and consumed contin-
 102 uously, but questions about the architecture of energy systems are posed with different
 103 temporal resolution. Also, information flows are often uncertain, and are resolved at

104 a variety of time scales. Predicting new technologies or policy changes, or the increase
105 in electrical demand due to transitions in domestic heating or transport, or the in-
106 stallation and closing of different generation plants can involve complex models and
107 forecasts and these can evolve over time within a physical or computational learning
108 process. Learning can lead to exponentially decreasing costs in new technologies, with
109 rates that are hard to predict a priori. Dealing with uncertainty in forecasts requires
110 models of some sophistication. In the short term, the intermittency of solar and wind
111 power requires backup supply in the form of fast-start generation, load reduction or
112 batteries, so that supply is reliable. On a longer time scale, energy might need to
113 be stored (e.g., in a hydro reservoir) for use in future months when the supply of
114 other sources of energy are lower. The aforementioned issues relate to parametric
115 uncertainties - things we know the form of but are unclear about their actual levels.
116 In contrast, model (or structural) uncertainty arises in problems that involve long-
117 lived capacity choices and need to account for many possible states of the world (e.g.,
118 emission constraints, technology changes, political environment) in future decades.

119 The third important dimension represents social and political or behavioral as-
120 pects. These can involve interplay with other (political) institutions, agencies (coun-
121 tries or adversaries) or policies and information. While we discuss models of behavior
122 related to (mathematical) game theory, this paper does not address social/political
123 factors or their evolution. Nonetheless, it is understood that interactions of these
124 types can affect the efficiency of designed systems and how local or national behavior
125 influences the outcomes of a given architecture.

126 The paper examines a number of policy questions arising in the green energy
127 transition that can be viewed in the above three dimensions. Despite the enthusiasm of
128 advocates for silver bullet solutions to the green-energy transition, the policy questions
129 that arise are complex and do not admit simple intuitive solutions. Our interest in
130 this paper is in formulating these questions in mathematical terms with a view to
131 representing the complexity of the tradeoffs involved. Problem formats that model
132 interactions, and determine what regimes are active at any given time are important
133 in understanding overall structure of solutions, even if specific details are abstracted
134 or approximated.

135 Our mathematical framework draws on two core methodologies: optimization
136 and game theory. Optimization is a powerful tool for exploring the tradeoffs that
137 are inevitable when comparing competing technologies. For example, it is tempting
138 to remove all fossil-fuelled electricity capacity from a region to make its electricity
139 100% renewable, but this might be very expensive compared with a system with 1%
140 of fossil-fuelled generation capacity that is used sparingly (see, e.g. [33]). System
141 optimization models make these tradeoffs explicit, and enable decision makers to
142 arrive at optimal combinations of technologies that will meet desired emission goals
143 at least cost. For models involving time and uncertainty, the optimization models
144 become more complicated, and must deal with estimates of probability distributions
145 and attitudes to and representations of risk.

146 The second methodology guiding our approach is game theory. The transition to
147 green energy emerging in most countries is driven by competing commercial agents,
148 responding to incentives and regulations set by governments. In its simplest form, this
149 setup is known by economists as a *principal-agent* problem [39], in which a leader takes
150 some action and a number of followers respond by optimizing their own objectives in
151 a competitive environment. There are many different versions of this simple game
152 model that arise from varying assumptions on the degree of strategic behavior of
153 agents and the knowledge that each agent has at their disposal. The models can

154 capture features such as barriers to entry, collaboration or contrasting risk attitudes.

155 In summary, the mathematical study of the architecture of green energy systems
 156 involves suites of models encompassing different resolutions in each dimension. The
 157 models can be optimized to determine some *social plan* of action that maximizes
 158 overall welfare subject to constraints, e.g., on emissions. This gives a gold-standard
 159 benchmark for more realistic policies that will attempt to achieve results through
 160 incentives (e.g., carbon taxes) and regulations (e.g., renewable energy standards).
 161 The extent to which the outcomes of these policies fall short of the gold-standard
 162 benchmark can be evaluated by game-theory models.

163 The paper is laid out as follows. In the next section we classify in mathematical
 164 terms the types of optimization and equilibrium models that will be applied to the
 165 various settings we study. Section 3 then describes a collection of example problems
 166 that can be studied using a selection of models cataloged in Section 2. Section 4 is
 167 devoted to a discussion of risk, and how one might devise models that represent the
 168 partial equilibrium that emerges when agents have contrasting risk measures. We
 169 then make some concluding remarks in Section 5.

170 **2. Mathematical Models.** Models are used in different ways in the sciences.
 171 They can be explanatory and promote understanding of unintended consequences
 172 through the revelation of counterintuitive linkages between decisions and outcomes.
 173 Our colleague, Tom Rutherford, remarked that it is always important to “show me
 174 a model in which this assertion makes sense”. But models can also be informative
 175 in a quantitative sense addressing questions such as: what is the size of a particular
 176 effect, or what will this policy or action cost? More recently, the notion of a data
 177 driven model (coming from the AI or Machine Learning communities) or the notion
 178 of a digital twin (that incorporates a model of some physical process) has become
 179 more prominent as AI has risen to the fore. This can be augmented by simulation
 180 modelling, defined as the process of creating and analyzing a digital prototype of a
 181 physical system to predict its performance in the real world, often as a parametric
 182 function of uncertain inputs. Approaches include the Monte Carlo method, agent-
 183 based modelling, discrete event simulation, and system dynamics modelling.

184 While there are many mathematical models that could influence the choice of
 185 architecture, we will confine ourselves in this paper to discussing approaches that
 186 are based in the field of optimization, and specifically to approaches that utilize
 187 constraints to model the underlying physical nature of the problems at hand. It
 188 is understood that any such model needs to be populated with data that instantiates
 189 these mathematical relationships. Different data will be relevant for models at dis-
 190 parate scales, but we will not cover the acquisition details of this. Nevertheless, we
 191 will consider the uncertain nature of these data and suggest models that account for
 192 this uncertainty using stochastic optimization approaches. In this section, we briefly
 193 outline the main formats that we will use in the sequel.

194 **2.1. Optimization models.** Our models will consider decision variables x that
 195 live in a finite dimensional space \mathbb{R}^n . These variables are constrained to lie in a subset
 196 X of \mathbb{R}^n and are used to define an objective function f that maps \mathbb{R}^n to the real line,
 197 and a vector valued function g that is constrained to lie in some convex cone K ,
 198 resulting in the optimization problem

$$199 \quad (2.1) \quad \min_{x \in X} f(x) \text{ s.t. } g(x) \in K.$$

200 Special cases of the data of this problem lead to formats under consideration, namely:

- 201 1. if f is a linear function, and g is an affine function, X is polyhedral (possibly
 202 \mathbb{R}^n) and $K = \{0\}^p \times \mathbb{R}^m$, then (2.1) is a linear program (LP)
 203 2. if in addition $X \subset \mathbb{Z}^{n_1} \times \mathbb{R}^{n_2}$ (i.e. some of the variables can only take on
 204 discrete values), then (2.1) is a mixed integer program (MIP)
 205 3. K can model both equations and inequalities or a mixture of both (as shown
 206 item 1 above)
 207 4. if f and g are convex functions of x then (2.1) is a convex optimization
 208 problem
 209 5. if ξ is a random variable defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and $f(x) =$
 210 $c(x) + \mathbb{E}_{\mathbb{P}}[Q(x, \xi)]$ where $Q(x, \xi)$ is the optimal value of the second-stage prob-
 211 lem

212
$$\min_y q(y, \xi) \text{ s.t. } T(\xi)x + Wy = h(\xi)$$

- 213 then (2.1) is a two-stage stochastic programming problem
 214 6. if in addition $X = \{x \geq 0 : Ax = b\}$, $c(x) = c^T x$ and $q(y, \xi) = q(\xi)^T y$, then
 215 the problem is a two-stage stochastic linear programming problem.

216 The formulation of the above two-stage problem assumes that the second-stage
 217 data ξ is modelled as a random vector with a known probability distribution. In many
 218 applications the expectation \mathbb{E} can be replaced by a more general risk measure ρ .

219 It is important to note that differences in terminology abound in the literature
 220 that deals with uncertainty in future events. In colloquial use the word “scenario”
 221 denotes a possible narrative of future events and decisions, so a scenario encapsulates
 222 both policy decisions and the outcomes that result from them. This terminology
 223 is used widely in the literature studying future decarbonization pathways. On the
 224 other hand, in the stochastic programming community, scenarios denote realized se-
 225 quences of random events that occur independently of any actions or policies. The
 226 scenario approach is then a technique for obtaining solutions to robust optimization
 227 and chance-constrained optimization problems based on a sample of an underlying
 228 random variable. Robust approaches often deal with worst-case outcomes, whereas
 229 probabilistic approaches deal with distributions. Acronyms such as LTA (learn-then-
 230 act or wait-and-see) compared with ATL (act-then-learn or here-and-now) can lead
 231 to misunderstandings of the underlying modelling approach.

232 Other data modelling issues are important to consider in stochastic programming.
 233 Often the notion of representative days are used for quantification of issues related to
 234 wind generation. Various papers explore the pros and cons of such approaches, see
 235 e.g. [62]. Also the spatial correlations between random variables modelling renewable
 236 generation can have distinct impact on the conclusions of a model that is informed
 237 by such data, see e.g. [75, 77]. Another correlation issue is the timing of failures after
 238 storms. The distribution seems to have delay or relates to the occurrence of multiple
 239 events.

240 It is possible to interpret policies specified by decision makers in different mathe-
 241 matical ways, some of which do not exactly capture the intended notion. Is a stated
 242 goal of zero carbon by 2050 to be interpreted as an almost sure constraint, or one that
 243 is to be satisfied with high probability [33]? Is the constraint “only once in 5 years”
 244 to be interpreted as a chance constraint, or the assertion that if the event occurs then
 245 it cannot occur again in the next four years. Models exploring these concepts are
 246 further discussed in [31].

247 The two-stage stochastic programming problem can be extended to a multistage
 248 stochastic programming problem, in which decisions are made in many stages $t =$

249 $1, 2, \dots, T$ and the random variables define a stochastic process $\xi_t, t = 1, 2, \dots, T$.
 250 After each stage t the values of ξ_t are realized, and adaptive decisions made in the
 251 light of this information. Such problems are useful in studying investment problems
 252 over long time horizons when new information might require existing capacity to be
 253 retired or replaced.

254 A useful special case of multistage stochastic programming is the discrete-time
 255 stochastic optimal control problem. Here the random variables ξ_t at each stage t are
 256 assumed to be independent of those at previous and later stages, and the decision
 257 variables divide into states x and controls u . This gives constraints:

$$258 \quad x_{t+1} = g_t(x_t, u_t, \xi_t), \quad u_t \in \mathcal{U}_t, \quad t = 1, 2, \dots, T - 1$$

259 and objective

$$260 \quad f(x) = \mathbb{E}\left[\sum_{t=1}^T f_t(x_t, u_t, \xi_t)\right].$$

261 In this case the problem has a finite horizon; infinite-horizon versions replace the sum
 262 in the objective with a discounted infinite series. Stochastic optimal control problems
 263 are amenable to solution by (approximate) dynamic programming [12, 72].

264 It is important here to be specific about the nature of the uncertainty in the above
 265 models. In most stochastic optimization problems, the random variables are assumed
 266 to have known distributions that can be estimated from a sample of historical data. A
 267 popular approach is to solve a sample average approximation problem using the finite
 268 empirical distribution [79]. Convergence of this approach with increasing sample size
 269 relies on laws of large numbers and the central limit theorem, which may not hold for
 270 heavy-tailed distributions. For stochastic optimization problems involving planning
 271 decisions made many years in the future, probabilities (e.g., of a new technology
 272 emerging) are impossible to estimate from historical data, and some expert assessment
 273 must be made and tested. As identified by Mercure et al [59], risks and opportunities
 274 in these settings are more important to identify than net present values based on
 275 discounted expected cash flow. A real-options [18] approach has some appeal here
 276 though this is difficult to apply in system settings where there are many competing
 277 and complementary investment options, and limited hedging instruments. Much of
 278 the work in the stochastic programming literature deals with problems with exogenous
 279 uncertainty (where the optimization decisions cannot influence the stochastic process).
 280 Decision dependent uncertainty problems [64] have endogenous uncertainty, and can
 281 model, for example, learning in systems.

282 Risk-averse stochastic programming problems formulated in scenario trees provide
 283 another alternative framework that models upside optionality as well as downside risk.
 284 Binary variables in these models can represent timing decisions, e.g. when to build
 285 or shut down generating plants, albeit with an increase in computational complexity.
 286 It is important to recognize that these models are *look-ahead* optimization models
 287 [71], with the goal of specifying a well-hedged first-stage decision. The intention
 288 after the first stage decision is implemented, is to re-solve a new model in a rolling-
 289 horizon fashion with updated estimates of parameters. How far to look ahead, how to
 290 appropriately approximate the future, and how to implement the solutions in practice
 291 are all interesting research questions, with answers that can generally only be settled
 292 by numerical experiments with context-specific models.

293 Finally in some settings one might seek a solution that performs well over a set

294 of varying problem data. *Robust optimization* provides a numerically efficient way of
 295 doing this by specifying a convex uncertainty set \mathcal{U} that defines the data variations
 296 (see [13]). For example, when the constraint data are uncertain we obtain:

$$297 \quad (2.2) \quad \min f(x) \text{ s.t. } x \in X(u), \quad u \in \mathcal{U}.$$

298 This notion can be extended to compute a *distributionally robust* solution to a sto-
 299 chastic optimization problem that performs well for every probability distribution
 300 lying in a set \mathcal{P} . An example formulation would be as follows.

$$301 \quad (2.3) \quad \min_{x \in X} \max_{\mathbb{P} \in \mathcal{P}} \mathbb{E}_{\mathbb{P}}[f(x, \xi)].$$

302 **2.2. Complementarity models.** A complementarity problem is a generaliza-
 303 tion of the optimality conditions of (2.1). In this setting we seek a variable x such
 304 that

$$305 \quad x \in X, F(x) \in X^*, x^T F(x) = 0$$

306 where $F : \mathbb{R}^n \mapsto \mathbb{R}^n$, X is now a cone (in many settings the positive orthant in \mathbb{R}^n)
 307 and X^* is the dual cone $X^* := \{w : z^T w \geq 0, \forall z \in X\}$. The third constraint indicates
 308 that x and $F(x)$ form a complementary pair and is often written as $x \perp F(x)$. The
 309 complementary slackness conditions of linear programming are a special case of a com-
 310 plementarity problem. While there are many examples of the use of complementarity
 311 formulations in engineering and economics (see [32, 35]), one particular modelling use
 312 allows the formulation to automatically switch between regimes of operation. For ex-
 313 ample, in [21] complementarity constraints are used to model automatic tap-changing
 314 transformers and other switched electrical devices. Given the following constraints,

$$\begin{aligned} 315 \quad & v = \bar{v} + v^+ - v^-, \\ 316 \quad & 0 \leq (q - q^{min}) \perp v^+ \geq 0, \\ 317 \quad & 0 \leq (q^{max} - q) \perp v^- \geq 0, \end{aligned}$$

319 it is easy to see that when q is strictly between q^{min} and q^{max} then v is at set point
 320 \bar{v} , whereas if q is at one of its bounds, then v is allowed to move away from the set
 321 point value.

322 A generalization of the complementarity problem is a variational inequality, where

$$323 \quad x \in X \text{ and } F(x)^T(z - x) \geq 0, \text{ for all } z \in X.$$

324 This is sometimes termed a generalized equation, since in the special case of $X = \mathbb{R}^n$
 325 it simplifies to the solution of a square nonlinear system $F(x) = 0$. It is also clear that
 326 when X is a cone, this is identical to the (cone) complementarity problem. When X
 327 is a convex set (not necessarily a cone), then the optimality conditions of

$$328 \quad \min_{x \in X} f(x)$$

329 are in the form of a variational inequality:

$$330 \quad x \in X \text{ and } \nabla f(x)^T(z - x) \geq 0, \forall z \in X,$$

331 when f is smooth enough. These are necessary and sufficient for optimality under a
 332 convexity assumption. For the optimality conditions of (2.1), where the constraints

333 $g(x) \in K$ have a particular representation, Lagrange multipliers can be introduced
 334 and the variational inequality are the so-called KKT-conditions. In this setting, a
 335 constraint qualification may be needed to prove equivalence to the optimization. The
 336 motivation to call this problem format an equilibrium problem arises from the consid-
 337 eration of the variational form of the Signorini problem [32]. Specialized techniques
 338 for solution are given in [53], for example.

339 A bilevel program is an example of a hierarchical optimization where a paramet-
 340 ric version of (2.1), the so-called lower level (follower) problem, is embedded in the
 341 constraint set of an upper level (leader) case of (2.1). Formally,

$$342 \quad (2.4) \quad \min_{(x,y) \in X} f_U(x,y) \text{ s.t. } g_U(x,y) \in K_U, y \in \text{SOL}_L(x)$$

343 where

$$344 \quad \text{SOL}_L(x) := \arg \min_{z \in Y} f_L(x,z) \text{ s.t. } g_L(x,z) \in K_L.$$

345 In other settings, SOL_L might consist of the optimal solutions of several linked
 346 optimization problems as in a non-cooperative game. Here the lower level problem
 347 $y \in \text{SOL}_L(x)$ can be replaced by a set valued inclusion $(x,y) \in \text{SOL}_L$ that represents
 348 a more general parametric equilibrium:

$$349 \quad (2.5) \quad \min_{(x,y) \in X} f_U(x,y) \text{ s.t. } g_U(x,y) \in K_U, (x,y) \in \text{SOL}_L$$

350 For example, there may be many followers $f_L(i)$, $i \in I$, where given the leader's
 351 policy choice x , the followers' actions are assumed to be chosen to give a *Nash equi-*
 352 *librium*, that is, no unilateral improvement for any follower. The leader seeks a policy
 353 that maximizes overall welfare. The mathematical formulation (2.5) of this problem
 354 is called a *Mathematical Program with Equilibrium Constraints* or *MPEC*. In fact,
 355 Mathematical Program with Equilibrium Constraints can encompass bilevel programs
 356 where the lower level parametric optimization problem is replaced by its variational
 357 form, thus

$$358 \quad \min_{(x,y) \in X} f_U(x,y) \text{ s.t. } g_U(x,y) \in K_U, y \in Y, \nabla_y f_L(x,y)^T(z-y) \geq 0, \forall z \in Y$$

359 where for notational ease we have simplified the lower level problem to

$$360 \quad (2.6) \quad \min_{z \in Y} f_L(x,z).$$

361 Assumptions are needed to guarantee that the variational form is necessary and suf-
 362 ficient for optimality in (2.6).

363 The principal-agent problem is an instance of the bilevel programming problem.
 364 In this case, the leader is the principal (owner) and the agent (manager) is the follower.
 365 The agent's actions $y = a$ are chosen to optimize their expected utility $V_A(w, a)$ given
 366 that the principal sets a reward $x = w$. The principal optimizes their expected
 367 utility $V_P(w, a)$. Note that the agent only accepts the contract if $V_A(w, a) \geq v_0$, so a
 368 participation constraint is added to the upper level problem. The bilevel form is thus:

$$369 \quad (2.7) \quad \max_{(w,a) \in X} V_P(w, a) \text{ s.t. } V_A(w, a) \geq v_0, a \in \arg \max_{z \in Y} V_A(w, z).$$

371 The last constraint in this model ensures that the chosen action is also the agent's
 372 best response. It is of course possible to convert this to an MPEC under assumptions
 373 that guarantee the lower level optimization can be replaced by its variational form.

374 **2.3. Machine learning models.** Dynamic models and the process of learning
 375 (both in the model and in the underlying system being modelled) is a critical part of
 376 both strategic and operational analyses. The problem of estimating the cost of new
 377 technologies and the evolution of these over time with large scale adoption/market
 378 entry is difficult and learning often generates much greater changes than anticipated
 379 in models [89]. This may be due to the large scale replication of some technologies and
 380 potentially gives advantages to the growth of these provisions over other alternatives
 381 (e.g. nuclear, or carbon capture and storage (CCS)) that have high development
 382 costs, isolated deployment and lack of learning. The paper [89] argues that principled
 383 use of these models, complete with confidence intervals related to uncertainties is an
 384 important tool in debates such as the one considered in this paper.

385 A second setting where learning a model (or a solution map) has enormous po-
 386 tential is the following, as advocated in [16, 87]. Suppose a particular aspect of the
 387 problem is captured by a (complicated) model, but formulating that within a larger
 388 model or decision process is difficult. Instead of using the explicit submodel, machine
 389 learning (or other stochastic modelling techniques) could be used to train a surrogate
 390 that is easy to use. That surrogate could be an approximation of the solution map (for
 391 example a deep neural net) of the submodel, or some alternative. Often the training
 392 of the surrogate model is expensive but can be done offline, possibly using advanced
 393 computing techniques to speed the process. However, once the surrogate is built, it
 394 is very easy, fast and cheap to use. While deep learning is stressed in the approaches
 395 cited above, other techniques such as SDDP [25] are also possible. An important
 396 application is to deal with security constraints or reliability, where these surrogates
 397 can be used in contingency checking for reserves design. There may be issues about
 398 prices when using such approximations are used and questions to address regarding
 399 out-of-sample performance. In many cases, the surrogate could be used to populate a
 400 lookup table for approximation of the original phenomenon. There is also an extensive
 401 literature on reduced order models [11] that have the same kinds of properties that
 402 are being advocated here, allowing the use of these models in multiple scale instances
 403 for example.

404 A specific example involves the learning of linear constraints (cuts) using machine
 405 learning. The context could be failure modes of an electricity system, where the
 406 original model is difficult, for example a non-convex AC optimal power flow (ACOPF)
 407 model. On loss of a transmission line, the “Latta formula” [68] is used to compute
 408 the flows on each of the resulting paths and the change in temperature induced then
 409 generates a time to failure. Currently constraints are added in “by hand” to guard
 410 against this possibility. Can we instead use a huge sample (offline learning) to generate
 411 a feasibility cut (rule of thumb replacement). Similar suggestions are found in [33]
 412 for a machine learning model trained to replicate hydro storage policies that could be
 413 used to inform the mix of other generation.

414 **2.4. Forecasting and prediction models.** There is an enormous literature on
 415 forecasting that utilizes methodologies such as deep neural nets, statistical learning
 416 [48] and data analytics. In this paper we assume such methods are used to generate
 417 forecasts that can be used for data provision in our models, but do not describe
 418 them further since their black-box nature makes it difficult to interpret results and
 419 understand the model constructs generated. Some references can be found in the
 420 following survey papers [46, 85].

421 **3. Examples.** In this section we look at examples of problems arising in the ar-
 422 chitecture of green energy systems that can be modelled using the approaches outlined

423 in Section 2. Our catalog of examples is loosely ordered by their scale, from the small
 424 to the large. Furthermore, the models are broadly conditioned on looking at issues
 425 of flexibility in planning, ensuring the problems determine decisions on technologies
 426 and capacities that are informed by operational characteristics of the desired energy
 427 system.

428 **3.1. Household electricity planning.** The simplest agent engaged in the tran-
 429 sition to green energy is the individual person or household. They make decisions on
 430 the level and type of energy consumption for heating, refrigeration, cleaning, enter-
 431 tainment, and transport. While there is an interplay between human behaviour and
 432 smart control systems, the increasing use of available information and optimized op-
 433 erations (e.g. via model predictive control) has the potential to reduce load and/or
 434 use green resources more fully. Households might choose to use a combination of
 435 rooftop solar energy, batteries and electric vehicles to meet their needs. If they are
 436 exposed to carbon charges and time-varying electricity prices, then they face a ca-
 437 pacity planning problem that chooses the capacity of heat pumps, solar panels, bat-
 438 tery and car battery, and an operating policy of electricity consumption and battery
 439 charging/discharging to meet expected energy needs. This is a two-stage stochastic
 440 program in which the first stage defines capacity choices and the second stage is an
 441 infinite-horizon stochastic optimal control problem that defines the operating policy.

$$\begin{aligned}
 442 \quad & \min_{z,x,u} K(z) + V \\
 443 \quad & \text{s.t. } V = \mathbb{E}\left[\sum_{t=0}^{\infty} \beta^t f_t(x_t, u_t, \xi_t)\right], \\
 444 \quad & z \in Z, \quad x_t \in \mathcal{X}(z, \xi), \quad u_t \in \mathcal{U}(z, \xi).
 \end{aligned}$$

446 Note that the constraint set Z can encode many complicated engineering relationships
 447 involving the investments z . The state variable x_t represents storage and the control
 448 u_t represents charge and discharge of storage as well as electricity purchases and load
 449 shedding. The set $\mathcal{U}(z, \xi)$ represents both household demand for electricity and supply
 450 of power from investments z . The operating costs $f_t(x_t, u_t, \xi_t)$ are discounted with
 451 discount factor β . Details and data for the capital, operating and lost load costs
 452 and the demand profile are not specified here, but represent samples for different
 453 operational cases. Of course, many households make investment decisions in solar
 454 panels and batteries without this sort of analysis as they are typically not exposed to
 455 varying electricity price and the household savings from optimal operations are too
 456 small to warrant the solution of a complicated optimization model.

457 While much of the energy management can be carried out “behind the meter”,
 458 agents might interact directly with the electricity market whenever they have a deficit
 459 or excess of power. Choices between purchase or load reduction (turning off appli-
 460 ances) can be price directed. Some companies install solar panel systems with built
 461 in controls that promise guaranteed electricity savings over a fixed time horizon, ob-
 462 viating the need for households to optimize individually. Such disaggregated control
 463 has some drawbacks as potential system stability problems may ensue if appliances
 464 of many agents respond simultaneously to a single price signal without some coordi-
 465 nation.

466 **3.2. Aggregators and micro grids.** Solar generation falls into two categories,
 467 residential (often called roof-top) and utility-scale (often called solar farms). Deter-
 468 mining the sizing of these farms is an optimization problem. Is it better to have a

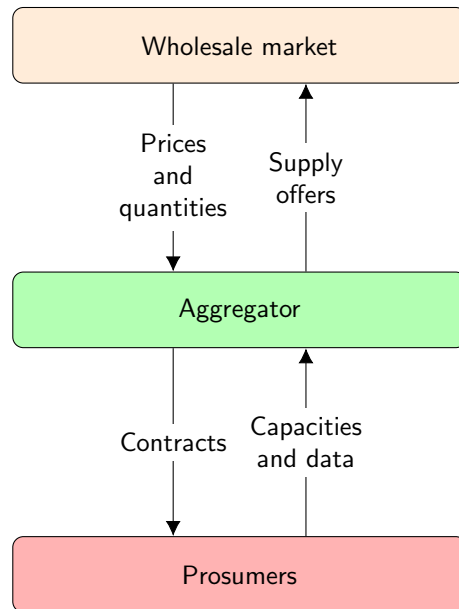

FIG. 2. *Aggregator as intermediary between prosumer and electricity market: based on [36]*

469 large single facility or a distributed collection of smaller ones? The answer will de-
 470 pend on land availability, and issues relating to the connection of this supply to the
 471 electrical grid.

472 Aggregators combine household demand and solar generation into a single energy
 473 source. This allows an aggregator to act as a virtual power plant and provide promises
 474 to deliver at least a certain amount of power/energy in a given time frame. These
 475 resources are part of a growing collection of distributed energy resources (DER), and
 476 their effective management and scheduling are mathematical problems that have re-
 477 ceived some recent attention [63]. Individual households typically cannot make such
 478 strong promises due to variability in the amount they can supply. Aggregation can
 479 reduce that variability, a property that is utilized to give diversified investments in the
 480 financial industry. Additionally, an aggregator can handle issues such as construction
 481 delays (a solar farm takes anywhere from 6 to 12 months to build), local and municipal
 482 permitting and approval processes, and ongoing maintenance and operation concerns
 483 [15]. The main concerns here are electrical engineering issues (and possible legality)
 484 related to distributed injection of supply, such as voltage support and frequency reg-
 485 ulation. Questions arise around the regulatory policy (see, e.g., [28]) vis-a-vis the size
 486 of the aggregate supplier, and also to whether innovations such as digital transformers
 487 can provide alternative technical solutions [60].

488 A schematic showing the typical operation of an aggregator system is shown in
 489 Figure 2.

490 Operational models for aggregators can vary. In [47], aggregators are the inter-
 491 mediaries between a collection of prosumers (the combination of a producer and a
 492 consumer) and the electricity market, whereas in [66] a different approach is taken
 493 where consumers are aggregated in a demand response setting. The aggregator's de-
 494 sign problem is to select from a collection of distributed solar energy sources those
 495 that in aggregate will generate a certain volume of energy with the smallest variation

496 in output (essentially the Markowitz model [58] in finance). We consider a design
 497 where solar energy sources are aggregated and augmented with batteries to smooth
 498 short-time fluctuations. If we let Q represent the matrix of covariances in energy
 499 output of solar sources, r be the vector of expected energy outputs, and $x = (x_i)$ be
 500 a binary variable that includes source i or not, we solve

$$\begin{aligned} 501 \quad & \min_{x \in X} c^T x + \varphi(x^T Q x) \\ 502 \quad & \text{s.t. } r^T x \geq d. \end{aligned}$$

504 X captures other constraints on x , and the objective adds the cost of solar installation
 505 to the cost $\varphi(\cdot)$ of batteries to deal with the overall variation in supply. The constraint
 506 then ensures average power output is above a threshold for interactions with the
 507 electricity grid.

508 In the context of distributed green energy systems, one concern is whether it is
 509 better to design the system for local use (i.e. use rooftop solar to power residential
 510 air conditioners directly behind the meter) and store excess locally in some form for
 511 later use (disaggregated storage), or is it better to directly deliver the excess to the
 512 electricity market, or have an aggregator manage the (excess) supply? These choices
 513 are compounded by supply intermittency when the local user has a deficit of energy
 514 and needs to procure it from elsewhere. The choice of storage mechanism is part of
 515 the design, and requires understanding the usage pattern - short or long time storage,
 516 power or energy requirements. In another section we touch on other aspects of storage
 517 or aggregated control related to reliability guarantees of the overall system.

518 Direct interaction with the market by a prosumer can be modelled as a special
 519 case of the aggregator problem. Interactions with the electricity market are governed
 520 by standard mechanisms described in Subsection 3.5. The remaining design decisions
 521 relate to the pricing of energy flows between the prosumer and the aggregator, and
 522 the mechanism to control the prosumer demand. For example, the aggregator can
 523 rent the consumer's roof at a fixed price, install its own solar panels, and then control
 524 the energy flows as part of a (large) virtual prosumer. An issue for the aggregator
 525 is to determine what roof space to rent and at what price (connection charge and
 526 per unit cost or payment), a so-called two-part pricing model. These models form a
 527 contract between the prosumer and the aggregator and such contracts can take on
 528 many forms. A rental contract could pay a fixed amount per month, or might provide
 529 retail power to the household at a reduced rate. The latter contract must specify how
 530 the price is indexed to the price of energy, and there is a need to understand how long
 531 term increases in demand will be treated, a topic that is well-understood by electricity
 532 retailers. Four different models of how to integrate distributed energy resources (DER)
 533 into electricity markets are given in [36]. They all rely on following a participant two-
 534 part pricing model (connection charge and selling price of the aggregator), but differ
 535 in the regulations that the aggregator faces.

536 Net metering is a billing method that allows consumers to use electricity they
 537 have generated at a different time than when it was actually generated. It's especially
 538 important for non-dispatchable renewable energy sources like wind and solar. An
 539 issue is the possible over-compensation for solar energy, and new policies are being
 540 generated to address this. Mathematical models could address related issues of fairness
 541 and equity.

542 Aggregation is also possible for plug-in electric vehicles that are currently con-
 543 trolled by their owners. Imagine a world where a fleet is owned and controlled by
 544 a corporation and cars are available on demand for a particular trip. This enables

545 the corporation to control charging and vehicle use using a similar model to those
546 outlined above.

547 **3.3. Distribution network architecture.** Distribution companies operate the
548 low voltage networks that distribute electricity from the high voltage transmission
549 grid to consumers. These operations are subject to variability from local demand
550 and generation but also from equipment failure. Distribution companies can install
551 special devices and configure the topology of the network to make it resilient to this
552 variability. Dynamic topology control that switches lines in and out of the network
553 also provides flexibility [34, 40, 41, 54]. For example, a mesh design (that provides
554 redundancy in the form of multiple connection paths) can be configured as a radial
555 network, allowing failures to be accurately identified and isolated. Lines (including
556 those that are switched out) can be reinforced to reconnect the distribution service
557 in case of failure (see for example [81]). In addition to these actions, the distribution
558 company can procure flexibility services from battery storage or interruptible load. In
559 a green energy system that has distributed battery capacity, these could be utilized for
560 short term supply during a reconfiguration process. The type and amount of services
561 to be procured depends on their offered cost, the existing flexibility actions available
562 to the distribution company, and the level of reliability they require.

563 Since the distribution network is largely radial, and flows are simpler to calculate
564 in this setting (similar to TCP/IP in internet applications), there is a tradeoff related
565 to the design of redundant links and their capacities. The idea is to have additional
566 lines built for reliability but switch them in and out to have a tree for flow calculation
567 and control. There is an extensive literature on this, related to tie lines, and back-
568 feeding. It is unclear if there are new issues related specifically to the green energy
569 transition.

570 **3.4. Load forecasting.** Estimating load on the electricity system is crucial for
571 many, if not all, models. Load forecasting is often categorized into: 1) Short-term (one
572 hour to one week), 2) Medium-term (week to a year), and 3) Long-term (longer than a
573 year) settings that are appropriate for different use cases. New policy issues, disruptive
574 technologies to facilitate the transition, engineering and economic enhancements that
575 change usage patterns, and efforts to electrify both heating and transport lead to
576 substantive changes in electric demand. In fact, the fast growth in the use of LLM's
577 across society and the world had led to huge increases in the use of computational
578 resources and consequently in energy to power them. Some see this as a principal
579 limitation to the AI revolution. Such perturbations must be included in the load
580 forecasts for them to be at all useful. A recent survey is provided in [65].

581 A popular approach is to use a neural network approach [6] for the load forecasts.
582 The paper [91] solves an optimal load dispatch model of a grid-connected community
583 microgrid which contains residential power load, photovoltaic arrays, electric vehicles
584 (EV), and energy storage systems (ESS), under three contrasting scheduling scenarios.
585 In the load dispatch model, the residential power load and the photovoltaic power
586 output were obtained from the forecasting results of a neural net model. The total
587 cost of the proposed model consists of transaction costs between the microgrid and the
588 main power grid, depreciation cost of EV and ESS, and treatment cost of pollutant
589 emissions. Simple limit constraints specify interaction with the electrical grid.

590 A related forecasting problem is that of determining the value of lost load (VOLL),
591 a single parameter that defines the price above which customers would wish to be
592 disconnected rather than consume energy. It is clear that such a price would be
593 different for every consumer, so a point estimate for VOLL is a coarse approximation.

594 Nevertheless, VOLL is widely used in security calculations and capacity planning
 595 models. These might benefit from a more nuanced model of demand reduction at
 596 high prices.

597 **3.5. Electricity system operations.** The economic dispatch model consists of
 598 buses \mathcal{B} , lines \mathcal{L} and generators $\mathcal{G} \subset \mathcal{B}$ in an optimization:

$$599 \quad (3.1) \quad \min_{(q, \theta, y) \in X} \sum_{i \in \mathcal{G}} c_i(q_i^g)$$

$$600 \quad (3.2) \quad \text{s.t.} \quad q_i^g - q_i^d = \sum_{j \in \delta^+(i)} y_{ij} - \sum_{j \in \delta^-(i)} y_{ji}, \quad i \in \mathcal{B}$$

$$601 \quad (3.3) \quad B_{ij}(\theta_i - \theta_j) = y_{ij}, \quad (i, j) \in \mathcal{L}$$

$$602 \quad (3.4) \quad -\bar{y}_{ij} \leq y_{ij} \leq \bar{y}_{ij}, \quad (i, j) \in \mathcal{L}$$

$$603 \quad (3.5) \quad q_i^{\min} \leq q_i^g \leq q_i^{\max}, \quad i \in \mathcal{G}$$

605 where $\delta^+(i) = \{j \in \mathcal{B} : (i, j) \in \mathcal{L}\}$, $\delta^-(i) = \{j \in \mathcal{B} : (j, i) \in \mathcal{L}\}$ specify the
 606 network structure, B_{ij} , $q_i^{\min, \max}$, \bar{y}_{ij} are electrical properties and c_i are production
 607 cost functions (most often linear or quadratic), and q_i^d is demand, see for example
 608 [84]. Variables determine active generated power q^g , voltage phase angles θ and
 609 active power flows y . Extensions of this basic problem can be used to incorporate
 610 different load conditions, failures, and maintenance schedules for instance (see for
 611 example [49]).

612 Locational marginal prices (LMPs), defined by the Lagrange multipliers (dual
 613 variables) on (3.2), can be shown to maximize total welfare of producers and con-
 614 sumers in perfectly competitive markets under assumptions of convexity and com-
 615 pleteness. Under some additional assumptions this is true in dynamic stochastic
 616 settings as well [30]. This feature is becoming important for renewable systems with
 617 storage.

618 Locational marginal prices are less attractive when optimizing systems with large
 619 thermal plant having minimum operating levels and fixed costs for switching on and
 620 off. In the setting above, we might add a constraint and binary variables x

$$621 \quad q_i^{\min} x \leq q_i^g \leq q_i^{\max} x, x \in \{0, 1\}$$

623 to force a particular generator to operate at 0, or in the range $[q_i^{\min}, q_i^{\max}]$, $q_i^{\min} > 0$.
 624 Here the lack of convexity invalidates the classical welfare theorems. In practice
 625 most system operators in LMP markets solve mixed integer programming problems
 626 to determine what plant should run, and when. Marginal prices from such a dispatch
 627 are not always sufficient to pay for generators' costs, and so "make-whole" payments
 628 are required to provide incentives for participation in the market. See [5] for a recent
 629 detailed discussion of the merits of such centrally dispatched systems in contrast to
 630 self-dispatched systems.

631 Some electricity market system operators (such as New Zealand and Australia)
 632 solve (convex) dispatch problems formulated as linear programs. To enable this they
 633 require supply curves to represent minimum operating levels and start-up and shut-
 634 down costs in the offered "marginal" cost curve. In other words, in a single-period
 635 setting, a plant that is currently off might mark up the marginal cost of its offer by an
 636 amount that would cover the cost of switching on if it were dispatched. A plant that
 637 was currently operating would offer at a discount to ensure that it was not switched
 638 off. Such a dispatch model treats these as truthful marginal cost declarations and

639 yields LMPs that reflect these. The welfare theorems of convex markets obviate the
640 need for make-whole payments.

641 There are two disadvantages with this approach. Unlike conventional marginal
642 costs that can be calculated from fuel costs and heat rates, amortized start-up and
643 shut-down costs are difficult to estimate. For example, should a start-up cost be
644 amortized over a 30 minute period or over the expected period that the unit is on?
645 To avoid a shortfall, suppliers will be conservative, and so the cost of dispatch will
646 generally be higher than one obtained by solving a MIP. This loss in efficiency will be
647 more pronounced when there are many large thermal units that can operate in dif-
648 ferent combinations. A MIP that accurately models starts and shuts can cut through
649 these to yield a less expensive dispatch.

650 A second disadvantage comes from the increased difficulty in monitoring the po-
651 tential strategic behavior of market participants who are now freed from any imposed
652 regulatory constraint to offer at short-run marginal cost. In markets that use MIPs
653 to dispatch generation plant, the start-up and shut-down costs and no-load costs are
654 also much harder to estimate than fuel costs, so there is admittedly a similar incentive
655 for generators to mark these up above their true values without being detected.

656 As electricity markets include growing amounts of intermittent generation and
657 storage devices, the make-whole payments required to incentivize participation have
658 been increasing (see [43]). While LMPS are currently computed using deterministic
659 models, the dynamic stochastic features of markets with green energy seem to require
660 a different approach to price formation to properly reward flexibility [26]. It is possible
661 that the replacement of coal and gas plant by wind and solar generators will decrease
662 economies of scale and lead to dispatch problems that can be well approximated by
663 convex stochastic optimization problems, reducing the need for make-whole payments.

664 Stochastic market clearing models have a new set of challenges, even if convexity
665 can be assumed. Even in markets approximated as a two-stage stochastic program
666 with a finite probability distribution the optimal solution cannot be both budget
667 balanced (where the independent system operator does not lose money) and recover
668 each agent's costs (each market participant does not lose money) in every scenario (see
669 [19]). It is possible under some strong assumptions on completeness of the risk market
670 to ensure budget balance and cost recovery in risk-adjusted expectation which at
671 least makes participation individually rational. A deeper philosophical problem with
672 stochastic dispatch is an assumption that agents agree on the underlying probability
673 distribution used in the stochastic program. Rather than imposing a distribution,
674 markets are supposed to be a mechanism for eliciting these probability distributions
675 from a range of participants who each "put their money where their mouth is".

676 Stochastic market clearing models must also be dynamic, treating many trading
677 periods at once, so they are stochastic optimal control problems rather than two-stage
678 problems. Since the realized values of random variables in the future will inevitably
679 differ from those in any model, the optimal control problems need to be updated in a
680 rolling horizon fashion, as these values are discovered. Currently, a number of markets
681 adopt this rolling horizon approach in a deterministic setting where single forecasts
682 are updated. Such look-ahead dispatch models can yield efficient dispatch solutions,
683 but can cause consistency problems in the resulting LMPs [42].

684 There is a large body of research related to non-convex models for electricity op-
685 erations and markets. Some of this is related to AC optimal power flow (ACOPF)
686 problems that are represented as non-convex nonlinear optimization models (or con-
687 vex approximations of these). Such models are typically more challenging to solve
688 compared with the linear models outlined above, and can be less favourable for analy-

689 ses due to a lack of accompanying duality theory. In addition to this, models of unit
690 commitment are also non-convex, typically modelled using mixed integer programs,
691 leading to concerns about the specification of energy prices. Much research continues
692 into the effective inclusion of these models into practice and the additional value to
693 the consumer that this facilitates, and that will be important while traditional gener-
694 ation (such as gas turbines used as backup) is still in operation. As we move through
695 the green transition, it is clear that the dynamic stochastic models will remain at
696 the cutting edge for operational considerations, but it may be that eventually the
697 non-convex ACOPF and unit-commitment issues will become less critical.

698 **3.6. Emissions trading.** Many countries have implemented cap-and-trade mar-
699 kets for greenhouse gas emissions [3, 86]. These differ in their implementation but
700 generally involve a decreasing cap on annual emissions permits that must be surren-
701 dered each year by organizations to account for their emissions. The permits are
702 auctioned by governments and traded in a secondary market. Given a price for a
703 permit each emitter in the economy faces an optimization problem that equilibrates
704 the price of permits against the marginal cost of reducing emissions.

705 In practice, emissions markets are subject to political intervention. Some sectors
706 of the economy (e.g. farmers whose animals emit biogenic methane) are made exempt
707 (at least temporarily) from surrendering permits. The reason is that the carbon charge
708 imposes a cost that they cannot avoid in the short term by technological means. Extra
709 costs might make them uncompetitive in international markets. This is unsustainable
710 in the long run, as biogenic emissions must be reduced. Indeed many countries are
711 beginning to add emission tariffs to imported goods, which effectively imposes the
712 costs on farmers that were not imposed by emissions charges in their own country
713 [61].

714 A second political intervention comes from the effect of emission charges on en-
715 ergy prices, notably gasoline and electricity. These price increases affect poor house-
716 holds disproportionately (as they spend a higher proportion of income on energy than
717 wealthy households). Moreover poor households have limited access to cheap capital,
718 so replacing legacy technologies such as gasoline cars and gas water heating is ex-
719 pensive. This results in strong advocacy for energy subsidies or for more substantial
720 income redistribution through taxation policy to enable poor households to reduce
721 emissions.

722 Ideally a global cap-and-trade market would result in a world carbon price that
723 would reduce emissions in the most efficient way. A number of authors (see e.g. [51])
724 have pointed to potential deficiencies in such a market. Lack of effective verification
725 of permits can cause “carbon leakage” to less compliant countries and weakening in
726 permit prices as experienced for about ten years after 2008. There are also potential
727 market failures. Consider a least-cost optimal solution for the world to reach a desired
728 emission target that requires a poor country to face a large fixed cost to be able to
729 reduce emissions (say by building a large hydroelectric dam). A global emissions
730 price might be insufficient to incentivize this. A subsidy from the rest of the world
731 will enable this solution to be realized.

732 A related issue is how to measure the carbon intensity in consumed products
733 or services. This is important for many companies who are aiming to demonstrate
734 their engagement in green energy practices. If a carbon price is incorporated into the
735 dispatch model, one could run simulations with and without that price, and observe
736 dispatch differences for example on a heat map. Allocation of these differences to
737 particular consumers requires new models. Another idea would be to fix the original

738 dispatch and run calculations through that solution to find instantaneous carbon
 739 intensities, and then integrate through time to get overall intensities. It is unclear
 740 how effective such calculations could be given all the other uncertainties in the process.

741 There is an analogy here with uplift payments in optimal dispatch, where the
 742 marginal energy price is insufficient to produce the socially optimal outcome. Uplift
 743 payments incentivize participation of all generating plant in the optimal dispatch
 744 solution.

745 **3.7. The role of storage, peaking and load shedding.** The most popular
 746 forms of green electricity are generated by the wind and the sun. These sources are
 747 both intermittent and uncertain. Intermittency (the fact that the sun does not shine
 748 at night) and the (random) variability (due to cloud cover or other effects) can be
 749 treated separately [90]. In some areas solar insolation is reasonably predictable but is
 750 not available at night time. If the solar power exceeds demand during the day and is
 751 not exported then some form of energy storage might be desirable to use the power
 752 generated during the day in the evening and night time. This storage is intended to
 753 be cycled on a daily basis, and will save its operators money by reducing night-time
 754 power consumption that must otherwise be bought off the grid [82]. Batteries are
 755 typically used to perform this function if the discounted electricity cost saved over
 756 the battery life covers its capital cost. Batteries also can be used to transfer energy
 757 between time periods for other variable sources of energy such as wind power [50].
 758 Specific mathematical models of batteries for use in storage models can be found in
 759 [73], for example.

760 Like any inventory, battery storage also plays a role when supply and demand are
 761 unpredictable [22]. Energy storage then provides a hedge against future uncertainty.
 762 The optimal sizing, location and operation of batteries under these circumstances
 763 requires a stochastic optimization model that represents the short-term uncertainty
 764 in supply, e.g., when predicted wind does not eventuate [94].

765 An alternative approach installs fast-start peaking generators to deal with un-
 766 certain and intermittent renewable energy supply. These typically are open-cycle
 767 natural gas turbines, but they could be configured to run on biofuel or green methane
 768 produced from carbon capture and hydrogen. The optimal sizing, location and op-
 769 eration of such peaking plant also requires a stochastic optimization model. Instead
 770 of installing peaking capacity, the system might arrange for (industrial) consumers to
 771 shed load in response to price. This *demand response* essentially performs the same
 772 function as a peaking plant. Estimating demand response for different customer types
 773 requires some estimate of their marginal value of electricity, which is much harder to
 774 determine compared with a price of natural gas. Another alternative is to use a bat-
 775 tery to provide the peaking functionality [23]. The related concept of *load balancers*
 776 is considered in the internet reliability literature. Load balancing techniques make
 777 internet operations more failsafe than electricity grid operations. It may be possible
 778 to leverage approaches such as those labelled “canary” to increase the reliability of
 779 the green energy grid.

780 Storage can also operate over a longer time scale (see [78]). For example in some
 781 regions where energy supply is seasonal, hydroelectric reservoirs are used to transfer
 782 water from melting snow or wet season rainfall to dry seasons of the year. The water
 783 in these systems stores energy. In contrast to short-term battery storage that can be
 784 used to overcome a limitation on electricity *capacity*, reservoir storage is a response
 785 to seasonal *energy* limitations.

786 Electricity markets have traditionally not needed to consider moving energy over

787 time and so their design is not necessarily ideal when the infiltration of storage devices
 788 and other methods to move load across time becomes significant. The use of stochastic
 789 programming models has drawbacks that include (a) the need to agree on the scenarios
 790 used for uncertain parameters in the model, and (b) the mispricing of the option value
 791 of energy storage and the value of increasing current dispatch to meet future ramping
 792 constraints, and (c) the need for uplift payments that compensate participants for the
 793 fact that the system operator forecast the future incorrectly. In a recent paper [69],
 794 we have proposed a new class of economic dispatch models that attempt to overcome
 795 these drawbacks, based on agent decision rules (ADRs). Forecasting future outcomes
 796 or scenarios passes from the system operator to market participants who make state-
 797 dependent offers of energy using these decision rules. When generators and battery
 798 owners face future uncertainty they take positions that risk losses. Some of these
 799 losses result from being dispatched in advance of a realized random price under which
 800 they would have preferred to be dispatched differently. In our dispatch model, we
 801 propose that the generators should factor this possibility into their ADRs. The ADRs
 802 will involve a short-run marginal cost and a state-dependent future cost function that
 803 enables the system operator to dispatch them in a single period optimization. ADR's
 804 can accommodate existing supply function bids, but also enable modelling of flexible
 805 load shifting, demand response and reserve bids.

806 **3.8. Transmission.** Electricity transmission architecture is a key component of
 807 the transition to green energy. Historically, transmission of electricity has been driven
 808 by economies of scale in generation. Electricity generation from large-scale coal and
 809 nuclear plant needs transmission to make it available to consumers that can be located
 810 many miles from generator locations. The cost of transmission lines has historically
 811 been low compared with the costs of proliferating small plants for local electricity
 812 generation. Even as these costs fall, transmission remains important since renewable
 813 sources of energy (e.g. offshore wind) are not always located where demand is.

814 In most electricity markets, transmission is separated from energy production, and
 815 is owned and operated by an independent regulated monopoly. Designing transmission
 816 systems to achieve desirable social outcomes is nevertheless a challenging optimization
 817 problem. Examples of models that study this are [57] in a deterministic setting, [88]
 818 in a setting with random wind and transmission switching, and [74] and [93] in a
 819 principal-agent setting.

820 For switching problems, the economic dispatch problem can be updated to replace
 821 constraints (3.3) and (3.4) by

$$822 \quad B_{ij}(\theta_i - \theta_j) - M_{ij}(1 - x_{ij}) \leq y_{ij} \leq B_{ij}(\theta_i - \theta_j) + M_{ij}(1 - x_{ij})$$

$$823 \quad -\bar{y}_{ij}x_{ij} \leq y_{ij} \leq \bar{y}_{ij}x_{ij},$$

825 for $(i, j) \in \mathcal{L}$, where M_{ij} represent so-called big-M constants that facilitate the switch-
 826 ing on and off of a given line ij , and binary variables x represent switching decisions.

827 Reconfiguration and initial design share many similar features, particularly if a
 828 given set of choices is specified a-priori. In this case, investment costs could be added
 829 to the objective:

$$830 \quad \sum_{i \in G} c_i(q_i^g) + \sum_{ij} b_{ij}x_{ij}.$$

831 **3.9. Energy/resource tradeoffs.** Land is finite, and using it for energy gener-
 832 ation such as in solar farms, or more generally for climate renewal as in reforestation,

833 precludes agricultural production or other uses. Similarly, biofuel production (corn
 834 for ethanol instead of feed) and dam building for new hydro generation uses land for
 835 energy while reducing its availability for other uses. In this context equilibrium mod-
 836 els are relevant, allowing a price to determine efficient allocation of scarce resources
 837 to a variety uses. Certainly, the tradeoff does not need to be limited to energy and
 838 land, but could involve other finite resources, or other environmental concerns.

839 As mentioned in the introduction, many forms of green energy may involve some
 840 use of finite resources. Batteries involve the extraction of rare-earth materials, and
 841 deforestation occurs in the extraction of copper. How can our models capture these
 842 effects? Do we need to consider more complex life cycle models accounting for all
 843 inputs, for example. Or is a pricing mechanism an effective way to encourage capital
 844 investment in alternatives?

845 More generally, energy generation and consumption is part of a broader economic
 846 landscape where energy and the products and services it enables are transferred be-
 847 tween different sectors of the economy. The effect of a change in the energy architec-
 848 ture will be felt in all sectors and requires a model of the whole economy to evaluate.
 849 Integrated Assessment Models (IAMs) of which there are many (see [67, 14]) aim to
 850 model these intersectoral energy flows in a system optimization framework. Alterna-
 851 tive approaches use computable general equilibrium models of the economy (see, e.g.,
 852 [92, 14]). Such models have already looked at the viability for example of biofuels,
 853 and could easily be adapted to other alternative technologies.

854 **3.10. Engineering and operational models.** The growth in green energy
 855 that is required to reach net zero might be less than projected if one focuses on the
 856 services that use energy rather than the energy that they currently consume. Ac-
 857 cording to [29], “Energy services are those functions performed using energy which
 858 are means to obtain or facilitate desired end services or states.” Consumer services
 859 might be redesigned so that they consume much less energy. Car and bike sharing are
 860 such services, others relate to batteries. Operations research models can determine
 861 prices, location of equipment and operational procedures to make these more effi-
 862 cient. Improvements can accrue from locating the service near to the source of energy
 863 generation or demand, with conversion from a storage entity occurring prior to use.
 864 Note that these models could benefit from an analogy to content delivery/distribution
 865 networks (CDN’s) in the internet delivery literature and practice.

866 Typical infrastructure planning models are also applicable to problems involving
 867 the type, quantity and siting of EV charging stations [9, 8]. Such models combine
 868 a node-based approach with a flow-based approach to model the needs of EVs to
 869 recharge on intermediary stops on long-haul travels, and uses a bilevel approach.
 870 Application to other infrastructure needs for the energy transition could build upon
 871 these and similar models. In general, it is possible to convert any form of energy
 872 into another target form, having different properties from the source form. Only
 873 40% of the energy used in the United States is currently supplied by electricity. The
 874 majority of the remaining 60% of energy is supplied by directly combusting fossil fuels
 875 like gasoline to power cars or by burning natural gas for heat and cooking.

876 **3.10.1. Conversion for Storage.** As mentioned above, electricity can be con-
 877 verted to a chemical form in a battery for example that allows for energy to be stored
 878 over short time periods, or water can be pumped uphill creating potential energy for
 879 later conversion using gravity and turbines. Such conversions are lossy, in that some
 880 energy is expended and lost in the conversion process. Electricity is expensive to store
 881 since it incurs these losses both in conversion and possibly over time due to leakage.

882 Storage also requires capital and this adds to the expense. Batteries have high
 883 conversion efficiencies but have a high capital cost per MWh stored. A principal use
 884 of batteries is therefore to transfer electrical energy over short time periods, allowing
 885 repeated use of the battery over time to arbitrage prices so as to recover capital costs
 886 from high utilization. The timing of charge/discharge can be determined effectively
 887 using stochastic control models.

888 For longer time frames of storage, batteries are not as effective since they are
 889 used less frequently and so cannot recover their capital costs. In this setting, there
 890 may be conversions of the electrical energy that are less efficient from an energy
 891 conversion perspective, but allow the energy to be moved across time to where it
 892 is much more valuable. These conversions may even be relatively inexpensive from
 893 a capital perspective, as they might only use excess capacity of existing/deployed
 894 technologies (such as ammonia generation or hydrogen to methane conversion). More
 895 generally, conversions could be done locally, converting generated energy into a form
 896 suitable for local storage and later use at that location or for more effective transport
 897 (e.g. methane is more easily transported in pipes with lower losses than hydrogen).
 898 Optimization again can be used to determine what conversions to do, where to do
 899 them, and at what scale.

900 **3.10.2. Portfolio of Storage.** System optimization models can shed light on
 901 these conversions and which ones are effective in a given portfolio. We illustrate this
 902 with a toy example. Consider a set K of different storage types (say ammonia, green
 903 methane, hydrogen, pumped storage, and battery), with variables for the amount of
 904 energy stored $s_{kt}(\omega)$ in storage type k in a scenario ω at time $t = 1 \dots, T$, and the
 905 related charging $q_{kt}^+(\omega)$ and discharging $q_{kt}^-(\omega)$ profiles. Integer variables x_k determine
 906 how many units of k are installed. The overall cost of operation is given by

$$907 \quad \sum_k c_k x_k + \mathbb{E}_\omega \left(\sum_t \gamma_k (q_{kt}^+(\omega) + q_{kt}^-(\omega)) + p_t(\omega) (q_{kt}^+(\omega) - q_{kt}^-(\omega)) \right)$$

908 where c_k is the per period capital charge for storage k , γ_k represents the cost due to
 909 cycling the battery and $p_t(\omega)$ is the price paid for energy at t . The system dynamics
 910 are modelled by

$$911 \quad s_{k(t+1)}(\omega) = s_{kt}(\omega) + e_k q_{kt}^+(\omega) - q_{kt}^-(\omega)$$

912 where e_k is the charging efficiency, and composition of the portfolio of storage is
 913 determined using

$$914 \quad s_{kt}(\omega) \leq \mathcal{S}_k x_k$$

915 with \mathcal{S}_k being the size of a unit of the storage k . Residual demand $r_t(\omega)$ is related to
 916 storage via

$$917 \quad r_t(\omega) = \sum_k q_{kt}^-(\omega) - q_{kt}^+(\omega)$$

918 This can be augmented with spill on the left hand side (that is penalized in the
 919 definition of cost perhaps) and the addition of a peaking plant supply on the right if
 920 desired. The key to such models is in the data $(K, T, c_k, e_k, \mathcal{S}_k, r_t(\omega))$: we specify T as
 921 the number of hours in a year, and generate the demand $d_t(\omega)$ uniformly at random

FIG. 3. Storage portfolio and charging frequency under different generation design scenarios.

922 (using an upper bound on the random sample in each time step generated by a seasonal
 923 underlying curve supplemented by daily deviations to capture the day/night cycles).
 924 Supply is specified so it provides an overbuild factor $1 + \eta$ more than the demand
 925 from generators, and residual demand is the difference of demand and supply. Other
 926 data are taken from estimates in the literature.

927 Figure 3 shows optimal installed capacity and the number of charge/discharge
 928 events for three different levels ($\eta = 0.2, 0.4, 0.6$) of renewable overbuild, in a free
 929 disposal regime without peaking plants. Installed battery capacity has high capital
 930 costs so the storage capacity chosen is small. It is used primarily to deal with demand

FIG. 4. *Optimizing renewable overbuild and storage*

931 peaks, so the frequency of its usage is large as shown in the lower panel of Figure 3.
 932 At low levels of excess renewable energy supply, the portfolio of storage investment
 933 is biased strongly towards the more efficient storage technologies (batteries and pump
 934 storage) to use the excess energy most effectively to avoid shortages. As the levels of
 935 renewable oversupply increase, ammonia and green methane become more attractive:
 936 the energy wasted by these less efficient storage technologies is less costly if there
 937 is a large surplus of energy and is outweighed by the lower capital cost of these
 938 technologies. Fewer batteries are built as oversupply increases, since this reduces
 939 peaking requirements that are increasingly handled by (less efficient) pump storage.

940 This simple model shows that a single choice of storage technology will not be
 941 optimal: we require a mix of storage technologies depending on the level of renewable
 942 overbuild. Of course the total costs of storage decrease as the amount of overbuilt
 943 renewable capacity increases, so there will be an optimal setting where the marginal
 944 cost of this equals the marginal decrease in storage cost. This is shown schematically
 945 in Figure 4. With an appropriate representation of the transmission network, the
 946 model can also be extended to determine the location of energy storage as well as its
 947 technology and size.

948 **3.10.3. Conversion for Transport.** Electricity is what we call a secondary
 949 energy source. It is created by converting primary sources of energy like fossil fuels,
 950 wind and solar energy, into electricity. It is a particularly useful form of energy because
 951 it can be quickly and efficiently transported over long distances and is readily usable
 952 in a multitude of settings (lighting, heat, mechanics, transport, etc). Electricity is also
 953 referred to as an energy carrier, which means it can be reconverted to other forms of
 954 energy such as mechanical energy or heat.

955 Transmission of electricity over long distances incurs losses through dissipated
 956 heat. (These losses are reduced by increasing the voltage and decreasing the electrical
 957 current.) The capital cost of the transmission infrastructure and the cost of energy
 958 losses can be compared with alternative forms of energy transport.

959 Since around only 40% of global carbon dioxide (CO₂) emissions originate from
 960 power generation which can be decarbonized via electrification, the other 60% coming
 961 mostly from industry, buildings and transport have to be decarbonized using alter-
 962 native means, one of which is green hydrogen. Green hydrogen is a versatile energy
 963 carrier that can be used directly or in the form of its derivatives like methanol or
 964 ammonia. Generating green hydrogen needs water (some regions are considering de-

965 salination to provide this) and uses various forms of electrolysis. One could imagine
 966 converting electricity to hydrogen gas at a large generation plant, transporting the
 967 hydrogen to a city, and then storing it and converting it back to electricity through
 968 combustion or fuel cells when it is needed. This enables the energy to be available at
 969 peak times. Note, however, that each conversion incurs a loss of energy and hydrogen
 970 is very expensive to transport (being light but requiring heavy pressure vessels, or
 971 susceptible to leaks from conventional gas pipes).

972 An alternative model transports electricity to the city and makes hydrogen lo-
 973 cally. Electrolysers to make hydrogen can be made cheaply at very small scale, and
 974 require only electricity and fresh water as fuel. This means that electricity rather
 975 than hydrogen is transported, and hydrogen can be made and stored locally where
 976 the demand occurs. Such a model requires a transmission grid to be dimensioned to
 977 meet extra demand, but avoids the much higher costs of hydrogen transport. The
 978 model in Subsection 3.10.2 can be easily extended to address these issues.

979 Demand for energy can change due to changes in behavior of users. There are
 980 concerns about the electrification of urban transport expressed for example in [17].
 981 While a very high gasoline tax would yield some interesting developments, it is unclear
 982 how elastic the demand is, and whether such policies would lead to more working
 983 from home, more use of public transport and electric vehicles. For another example,
 984 air transportation is very energy intensive and currently not very green. Transition
 985 strategies are focused on sustainable aviation fuel (SAF), liquid hydrogen and electric
 986 power, both pure and hybrid [38]. The aggregation of transport by sea or pipeline
 987 instead of airlines or trucking could reduce emissions substantially, perhaps at the
 988 cost of longer transport times. Passenger travel via sea instead of by air might also
 989 involve much longer times, but at a smaller energy cost per person. Models could
 990 shed light on the underlying properties that are being utilized here - is the key simply
 991 economies of scale? Tradeoffs based on behavior change are not limited to the energy
 992 sector but will impact other sectors such as tourism and industrial productivity.

993 **4. Risk.** In the classical finance literature, risk is identified with variance. In
 994 some settings this makes it beneficial to reduce variance through aggregation. As in
 995 the model of Subsection 3.2, a collection of wind turbines with uncorrelated variable
 996 wind generation can be aggregated to give a more predictable supply, which presents
 997 advantages to economic dispatch models. Similarly the capital asset pricing model
 998 translates variance in returns into a discount rate that can be used to assess the risk
 999 of uncertain cash flows, so reducing variance with no change in expected reward is
 1000 deemed to be beneficial.

1001 However, as noted by [59] the energy transition presents decision makers with
 1002 risks (downside variance) and opportunities (upside variance). Ideally, optimization
 1003 models should be able to take advantage of opportunities while minimizing risks.
 1004 In contrast with models that minimize variance, risk-averse stochastic programming
 1005 models using *coherent* risk measures [79] provide a principled approach for doing this.

1006 Risk in settings with many agents requires careful handling. Each agent type
 1007 is exposed to a unique set of risk factors that arise from their technology choices,
 1008 climate, fuel source, exchange rates, and regulatory intervention. Some of these risks
 1009 can be reduced through hedge contracts signed with counterparties who see reward
 1010 opportunities in the risks faced by others. We give some examples of these transac-
 1011 tions.

1012 **4.1. Short-term risk instruments.** A popular form of hedge contract is called
 1013 a *contract for differences* (CFD). Arranged at some strike price f , this is a financial

1014 agreement to pay a counterparty $p - f$ where p is the observed price of electricity.
1015 So if party A intends to sell Q MWh to counterparty B at some future time, then Q
1016 CFDs arranged at f will hedge the unknown future price and conduct the transaction
1017 at known price f .

1018 Weather derivatives are also a mechanism for reducing risk. Consider distributed
1019 solar, and demand from air-conditioning. In the event of a very sunny day, the air
1020 conditioners need more energy to run and the price would rise, but solar farms are
1021 producing more. A weather derivative in which the solar farm guarantees the air
1022 conditioner a certain amount of energy whenever the temperature (or insolation) is
1023 above a certain level will reduce the risk of losses of both parties.

1024 For a second example of weather-based derivatives consider a geothermal genera-
1025 tor. This has high capital costs and very low operating costs, so it make sense to run
1026 as a base-load plant. In the middle of the day when solar power is at a maximum,
1027 it might make sense for the electricity system to control geothermal output to avoid
1028 spilling energy. A solar farm might arrange a derivative contract with a geothermal
1029 plant that pays out when the sun shines, but imposes a cap on geothermal output at
1030 this time [44].

1031 Can hedge contracts remove all risk? In an uncertain environment an *Arrow-*
1032 *Debreu security* is a derivative contract that pays \$1 to the holder if a particular
1033 future state of the world occurs. If these exist for every possible future state then in
1034 principle an agent can insure against any conceivable loss (at some ex-ante cost) by
1035 purchasing an appropriate Arrow-Debreu security off a counterparty.

1036 This highly idealized situation would never occur in practice but it is a useful
1037 model to study risk and contracts. A relatively recently developed theory (see [76, 70,
1038 30]) shows that if markets for energy are perfectly competitive and convex, and all
1039 agents are endowed with coherent risk measures, and the market for Arrow-Debreu
1040 securities is complete, then agents will trade their risk using these securities until
1041 no more risk can be hedged. The remaining risk is then treated by each agent as
1042 if they were using the risk measure of the least risk-averse agent. For example if
1043 some agents such as speculators were actually risk-neutral then a complete market
1044 for Arrow-Debreu securities will result in every agent optimizing the expectation of
1045 their costs and benefits (i.e., acting as neutral to risk). This theory enables one to
1046 establish useful welfare theorems that demonstrate that the markets deliver socially
1047 optimal outcomes.

1048 In practice, risk markets are incomplete, so the welfare theorems do not hold.
1049 Computational studies show that removing some risk using CFDs and other instru-
1050 ments can improve welfare outcomes in incomplete markets. It is also possible to find
1051 counterexamples where adding instruments makes welfare worse [4]. Furthermore the
1052 computation of equilibria in incomplete settings is difficult as these might fail to exist
1053 or not be unique [37]. This is an active area of research in scientific computation (see,
1054 e.g. [52, 45]).

1055 **4.2. Long-term risk.** The transition from a largely fossil-fueled energy system
1056 to a renewable system is expected to take decades. Although we can develop sophis-
1057 ticated planning models to guide the decisions made, these decisions will in many
1058 cases be made by commercial organizations in pursuit of profits, but also facing many
1059 uncertainties. Investment in energy production and infrastructure development is fi-
1060 nanced largely by borrowing, and the cost of this finance depends on the risk of the
1061 investment, and so organizations making investment decisions need to understand the
1062 risk of the investment as well as its (uncertain) reward.

1063 Capacity investments must make non-negative risk-adjusted returns to be justi-
 1064 fied. In the risk-averse stochastic programming setting this amounts to a non-negative
 1065 net present value with stochastic discount rates. In a complete market for risk, the
 1066 trade of Arrow-Debreu securities leads companies to share the same stochastic dis-
 1067 count rates. This allows the optimal capacity decisions for companies to be determined
 1068 by a social planner who maximizes social NPV with the same discounting.

1069 In practice, as in the short-term setting, risk markets are not complete, so a social
 1070 planning solution might not match a risked equilibrium. The latter, however, can often
 1071 be computed as the solution to a complementarity problem. As an example, consider
 1072 the following equilibrium problem formulated in [19] where each generator chooses
 1073 generating capacities and generation levels and retailers of energy choose amounts to
 1074 buy¹. Each agent a solves the problem:

$$\begin{aligned}
 1075 \quad P(a) : \quad & \min_{(\mathbf{x}^a, \mathbf{z}^a, \mathbf{q}^a) \geq 0} \rho^a(Z^a) \\
 1076 \quad & \text{s.t. } Z^a(\omega) = \sum_{k \in \mathcal{K}} K_k \cdot z_k^a \\
 1077 \quad & + \sum_{t \in \mathcal{T}} \sum_{k \in \mathcal{K}} (c_{kt}(\omega) - \pi_t(\omega)) \cdot x_{kt}^a(\omega) \\
 1078 \quad & + \sum_{t \in \mathcal{T}} (\pi_t(\omega) - r) \cdot (d_t^a(\omega) - q_t^a(\omega)) \\
 1079 \quad (4.1) \quad & + \sum_{t \in \mathcal{T}} v \cdot q_t^a(\omega) \qquad \qquad \qquad \forall \omega \in \Omega, \\
 1080 \quad (4.2) \quad & x_{kt}^a(\omega) \leq m_{kt}(\omega) \cdot z_k^a \qquad \qquad \qquad \forall k \in \mathcal{K}, \omega \in \Omega, t \in \mathcal{T}, \\
 1081 \quad (4.3) \quad & \sum_{t \in \mathcal{T}} x_{kt}^a(\omega) \leq n_k(\omega) \cdot z_k^a \qquad \qquad \qquad \forall k \in \mathcal{K}, \omega \in \Omega \\
 1082 \quad (4.4) \quad & q_t^a(\omega) \leq d_t^a(\omega) \qquad \qquad \qquad \forall \omega \in \Omega, t \in \mathcal{T}.
 \end{aligned}$$

1084 The objective for each agent, a , is to minimize their own risk-adjusted disbenefit
 1085 $\rho^a(Z^a)$. Here ρ^a is a coherent risk measure and $Z^a(\omega)$ is the net cost from invest-
 1086 ing and operating their fleet of generation in scenario ω as defined by (4.1). The
 1087 constraints contain terms for both generators and retailers and so some will not be
 1088 present for each type of agent. The generator a produces $x_{kt}^a(\omega)$ from plant type k
 1089 and the retailer buys power at wholesale price $\pi_t(\omega)$ and sells it at fixed price r . In
 1090 the first line of (4.1), we have the physical capacity investment cost, $\sum_{k \in \mathcal{K}} K_k \cdot z_k^a$,
 1091 where the sum is over investment technologies. In the second line of (4.1), we have
 1092 the component of the disbenefit from generation, $(\mathbf{c} - \boldsymbol{\pi})\mathbf{x}$, with \mathbf{c} giving the marginal
 1093 cost of generation, $\boldsymbol{\pi}$ the spot market price, and \mathbf{x} the output of generation.

1094 In the third term, we define the disbenefit from meeting demand. The per unit
 1095 cost of meeting demand is given by $\boldsymbol{\pi} - \mathbf{r}$ with the agent having to purchase the
 1096 electricity directly from the spot market at $\boldsymbol{\pi}$ and given \mathbf{r} by the consumer. The
 1097 demand met by the retail component of the agent is given by $\mathbf{d} - \mathbf{q}$. The exogenous
 1098 demand of each consumer is given by \mathbf{d} , and \mathbf{q} is how much the retail company decides
 1099 to curtail. The overall profit is given by $(\boldsymbol{\pi} - \mathbf{r})(\mathbf{d} - \mathbf{q})$.

1100 In the final term, we define the penalty the retail agent must pay for unmet

¹In [19] there is also an ISO agent that dispatches power through a transmission network. We assume a single node model for simplicity.

1101 demand, \mathbf{q} . The penalty is the value of lost load, \mathbf{v} , which is much higher than
 1102 typically observed spot market prices. This penalty is added to the lost revenue from
 1103 not meeting all of the consumer demand for electricity generation.

1104 In equations (4.2) through (4.4), we define the physical constraints on generation
 1105 and curtailment. Equation (4.2) limits the power output \mathbf{x} of each plant, depending
 1106 on the capacity investment \mathbf{z} and some multiplicative adjustment, \mathbf{m} , that depends on
 1107 the scenario and load block. Equation (4.3) limits the energy output of a generation
 1108 plant. Finally, (4.4) limits consumption to be at most the level of demand.

1109 To form a complementarity problem, the KKT conditions from problem $P(a)$ for
 1110 each agent a are added to the following market clearing conditions:

$$1111 \quad 0 \leq \sum_{a \in \mathcal{A}, k \in \mathcal{K}} x_{kt}^a(\omega) + \sum_{a \in \mathcal{A}} q_t^a(\omega) - \sum_{a \in \mathcal{A}} d_t^a(\omega) \perp \pi_t(\omega) \geq 0, \quad \forall \omega \in \Omega, t \in \mathcal{T},$$

$$1112 \quad 0 \leq \sum_{a \in \mathcal{A}} q_t^a(\omega) \perp \mathbf{r} + \mathbf{v} - \pi_t(\omega) \geq 0, \quad \forall \omega \in \Omega, t \in \mathcal{T}.$$

1113

1114 These complementarity conditions ensure that supply meets demand at a competitive
 1115 price. We have free disposal of power within our model, allowing supply to exceed
 1116 demand at each node. However, when this occurs, the spot market price for electricity
 1117 at this node will be 0. And when some positive amount of load is shed then the price
 1118 hits its maximum value $\mathbf{r} + \mathbf{v}$. As mentioned above, the incompleteness of the market
 1119 for trading risk complicates the existence, uniqueness and computation of equilibrium
 1120 in these models, but in many practical instances equilibria exist and can be computed
 1121 (see [55] and [4]).

1122 As alluded to by [59], long-term investment decisions should maximize opportu-
 1123 nity while controlling risk. Stochastic programming models that represent such real
 1124 options are multistage, since opportunities are revealed over time as random variables
 1125 are realized. Multistage risk-averse optimization has many variations depending on
 1126 the form of conditional risk measure used. We mention two.

1127 Given an adapted set of actions at each node of a scenario tree, an *end-of-horizon*
 1128 risk measure sums the payoffs at each node along a path from root to leaf to give a
 1129 scenario payoff. The risk of the set of actions is then evaluated using a coherent risk
 1130 measure applied to this distribution of scenario payoffs. This is the predominant risk
 1131 measure used in software for solving multistage models of capacity expansion under
 1132 uncertainty (see, e.g., [24]).

1133 Given an adapted set of actions at each node of a scenario tree, a *nested* risk
 1134 measure computes the risk-adjusted payoff at the parent of each leaf node, using the
 1135 payoffs at this node and its children. This risked “value-to-go” function is then used
 1136 to evaluate the risk-adjusted payoff of the set of decisions at the grandparent of each
 1137 leaf in a recursive pattern. This recursive definition ensures that the dynamic risk
 1138 measure is time-consistent.

1139 Dynamic risked equilibrium (see [30]) of many agents can be viewed as an open-
 1140 loop problem or a closed-loop problem. In the former setting, agents choose every
 1141 action in every state of the world on day 1, assuming other agents have fixed theirs.
 1142 The response of an agent is then computed in response to this knowledge. Such an
 1143 equilibrium is not subgame perfect. In a closed-loop equilibrium, an equilibrium is
 1144 computed for every state of the world at the final time. The payoffs in this equi-
 1145 librium then inform actions at the penultimate time, and the solution is computed
 1146 recursively. As shown in [30], these two solution concepts yield the same result in
 1147 perfectly competitive convex markets with complete risk markets. In imperfect or

1148 incomplete markets they are not the same. Developing computational methods for
 1149 these problems is an active area of research (see [80]).

1150 Why are these models important? Much effort has been devoted to developing in-
 1151 tegrated assessment models (IAMs) for understanding the transition to green energy.
 1152 These models are (often deterministic) social planning models with high levels of phys-
 1153 ical fidelity, but treating the future as predictable scenarios. Including uncertainty
 1154 and risk aversion in these models makes them more realistic, but the results need
 1155 to be reconciled with commercial investment decisions of competing agents. Welfare
 1156 theorems give some justification for using risk-averse IAMs as gold-standard bench-
 1157 marks for the dynamic risked equilibria in incomplete markets that we believe are
 1158 closer representations to what will actually occur.

1159 **4.3. Architecture for resilience.** Unexpected outages (that can arise from
 1160 operator mistakes, major storms or environmental disturbances, or even deliberate
 1161 sabotage by adversarial actors) are a general concern in electrical energy systems.
 1162 However, the more distributed nature of green energy systems may allow some en-
 1163 hancements, whereby cascading failures can be avoided by isolating subnetworks of
 1164 the overall grid. Since more batteries or other storage devices are installed (to provide
 1165 transfer of energy over time), those same resources could be made available (along with
 1166 existing distributed generation) to facilitate balancing while isolated. This is a novel
 1167 use of additional functionality installed in the system to improve overall resilience.

1168 In any disaggregated system, the need arises for additional information to facil-
 1169 itate better overall control and stability. There is a large existing literature in the
 1170 energy domain related to information, privacy and mechanism design (for markets,
 1171 auctions, etc). The underlying question regarding the much finer scales of disaggrega-
 1172 tion that might come about in a green energy system brings up questions as to whether
 1173 these existing mechanisms are sufficient in these new operating environments, or what
 1174 changes and enhancements are needed. An alternative approach is outlined in [77].

1175 **4.4. Capacity markets.** The transition to green energy will be costly. Accord-
 1176 ing to the International Energy Agency over 60% of the world's electricity in 2021
 1177 was generated from fossil fuels. Given that total electricity generation will increase
 1178 from electrification of transport and industrial processes, the scale of the investment
 1179 in green electricity capacity is immense.

1180 This raises several important questions. What incentive structures are needed
 1181 to ensure that the right mix of capacity is built? Is the dynamic risked equilibrium
 1182 that emerges from commercial decisions enough to give the capacity increases that we
 1183 need? Finally, will this equilibrium be achieved in time to avert a climate catastrophe?
 1184 As an aside, the US is experiencing large interconnection queues [56] for the approval
 1185 of new wind and solar projects. Models to explain this process are developed in [7].

1186 The first question is an area of active research. As mentioned in Subsection 3.5
 1187 locational marginal prices (LMPs) are not always sufficient to incentivize optimal par-
 1188 ticipant behavior. In perfectly competitive, convex energy-only markets LMPs provide
 1189 economic rents that support optimal levels of investment at the margin determined
 1190 by a *screening-curve* analysis [83] as depicted in Figure 5.

1191 The screening curve shows the annual total cost per MW capacity plotted against
 1192 the number of annual operating hours. The total cost is a combination of fixed and
 1193 variable cost based on the number of production hours in a year. A minimum cost
 1194 for each capacity factor can be found by combining the screening curve with the *load*
 1195 *duration curve* (LDC), here approximated by 10 load blocks with piecewise constant
 1196 demand. The projection produces the least-cost capacity combination that can serve

FIG. 5. The screening curve: how capacity is traditionally planned in electricity systems.

1197 the load profile. For example, to supply the part of the LDC that has higher capacity
 1198 factor (*i.e.*, running most of the year), base load is the least cost option. As the
 1199 number of operating hours decreases, the plants that are less expensive to build but
 1200 more costly to run begin to become more economical. For a small number of hours
 1201 near the tip of the duration curve, high variable cost peakers are the most economical,
 1202 while some load is shed at VOLL.

1203 This picture is complicated by intermittent generation sources that are not dis-
 1204 patchable, and by risk aversion that affects the equilibrium as discussed in the previous
 1205 section. And even in the simple deterministic case, energy prices might need to be
 1206 very high on occasions to sustain the peaking investment needed to make the system
 1207 avoid shedding load. For example if load shedding is acceptable in at most four or five
 1208 hours per year, then prices need to become very high to pay for the annual capital cost
 1209 of a peaking plant that runs only during these periods. The uncertainty of receiving
 1210 these cash flows every year makes such an investment too risky.

1211 Contracts between energy suppliers can resolve some of the risks faced by gener-
 1212 ators in deciding capacity investments. For example, a hydroelectric generator could
 1213 arrange a two-way option contract with a coal plant to keep the coal plant available
 1214 for periods of low reservoir inflows. The hydroelectric generator buys a call option
 1215 off the coal plant, and the coal plant buys a put option (at a lower strike price) from
 1216 the hydro generator. These contracts (that can be arranged to have the same price)

1217 enable the coal plant to receive revenue even when wholesale prices are below its
1218 marginal cost of generation in return for some loss of revenue in peak periods.

1219 *Capacity markets* that arrange additional payments for committed generation
1220 capacity ahead of time are a popular mechanism intended to overcome these problems.
1221 Opinions differ on the effectiveness of these mechanisms in comparison with energy-
1222 only markets, and studying their design and operation is an active area of research.

1223 In dealing with the transition to green energy, capacity markets serve to answer
1224 the second question as they can procure the desired capacity of different energy tech-
1225 nologies at auction. So governments can decide to increase this as needed to meet
1226 demand growth. It is not clear whether the same outcome might be achieved at lower
1227 cost with an energy-only solution.

1228 Large-scale expensive new generation capacity expansion requires electricity de-
1229 mand to pay for it. One source of this is private, behind-the-meter specialized ap-
1230 plications such as data centers or large industrial concerns. One might expect to see
1231 generation capacity expansion occur behind the meter backed by such demand.

1232 The final question of timing is important. A green-energy risked equilibrium must
1233 be viewed over a long time scale and achieve a green energy system in time to avert
1234 a climate catastrophe. Dynamic equilibrium models might give some confidence that
1235 commercial investment will deliver in time, but betting the planet's future on this
1236 might be too risky for policy makers. As evidence of climate change becomes more
1237 obvious, generational shifts in voter preferences might lead to more direct government
1238 intervention in planning and implementing the transition. In this case, relying on com-
1239 petitive electricity markets to achieve the transition might be viewed by governments
1240 as too much of a risk.

1241 **5. Conclusions.** In this paper we have outlined some of the questions arising
1242 in the transition to green energy, and presented some mathematical approaches to
1243 address them. The models we discuss are formulations of optimization problems
1244 and related complementarity problems, in settings with a variety of physical scales,
1245 and dealing with different time scales. The costs of the physical and institutional
1246 architecture required to bring about the transition will be substantial and will involve
1247 risk. Mathematical models will be essential in understanding the complex tradeoffs
1248 that have to be made in planning and incentivizing the transition to enable it to occur
1249 at a low cost and in time to avoid global temperatures rising to unacceptable levels.
